The present invention relates to a method of supplying fluids under pressure and of heating fluid, particularly hot pressurized water, by heat exchange in a reactor cooled by a cold fluid. This method may be used in particular in the pressurized water reactors (PWR), which are supplied by a pressurized fluid. In a pressurized water nuclear reactor (PWR), a primary cooling circuit is used to remove the heat from the reactor. This cooling circuit, also termed cold fluid circuit, is constituted by primary pumps, heat exchangers and piping. The cooling circuit generates a liquid flow which circulates around the reactor, the work done by this flow being, in the majority of the cases, used to produce electricity. This circuit is cooled by generating a heat transfer between the cold liquid and the reactor, which is used to remove the heat from the reactor. The cold liquid in contact with the reactor is generally water, which is the so-called coolant of the reactor. This water flows in the primary circuit of the reactor through the heat exchangers and then through the pumps which return it to its initial temperature. The hot reactor water returning from the pumps is then routed to the secondary circuit of the reactor, which is water from an external source. The secondary circuit receives hot water from the external source and returns it to the cold fluid circuit, i.e. water which is at ambient temperature, so that the heat exchange with the reactor may continue. In the pressurized water nuclear reactors the circulating flow of water is kept in a turbulent zone throughout the pipe by means of a flow rate of water which is higher than the natural flow of the water, i.e. when the pipes are not damaged or clogged. Thus, the turbulent nature of the flow of water throughout the pipes makes it possible to remove greater quantities of heat from the pipes. It is also possible to use a tube that is smaller than that normally used in the pipe network, due to the turbulence of the flow of water, which allows it to be used as a heat exchanger. Furthermore, this turbulence of the flow of water, at least in certain locations, helps maintain the reactor in a saturated condition and makes it possible to cool it, even though there is the possibility of a leak in one of the pipes or nozzles of the reactor.

An often necessary operation
